Proper time accumulated by the spaceship clock along the trajectory $\mathcal{P}$:

$$\Delta \tau[\mathcal{P}] = \lim_{N \to \infty} \sum_{i=1}^{N} \Delta \tau_i = \int_{\mathcal{P}} \frac{ds}{c} = \int_{t_D}^{t_A} dt \sqrt{1 - \frac{v^2(t)^2}{c^2}}$$  \hspace{1cm} (2.25)

- As constructed, the proper time $\Delta \tau[\mathcal{P}]$ of a time-like trajectory $\mathcal{P}$, parametrized by $\hat{x}(t)$ for $t \in [t_0, t_1]$, is the time elapsed by a clock that follows this trajectory in spacetime.
- This result is valid for accelerated clocks.

In general, special relativity can describe the physics of accelerated objects as long as the description of the process is given in an inertial coordinate system (as is the case here).

- The right-most expression in Eq. (2.25) yields the same result in all inertial systems $K$ [recall Eq. (2.24)]. This is why $\tau[\mathcal{P}]$ is a function of the event trajectory $\mathcal{P}$ and not its coordinate parametrization $\hat{x}(t)$. This is important: It tells us that all inertial observers will agree on the reading of the spaceship clock $\tau_A$ at arrival $A$ (although their parametrization $\hat{x}(t)$ may look different).

- Note that since $\hat{x}(t)$ is assumed to be time-like, it is $\forall t : |\hat{x}(t)| < c$ such that the radicand is always non-negative.
- $\tau[\mathcal{P}]$ is a functional of the trajectory $\mathcal{P}$; this is why we use square-brackets.

4 | Which trajectory $\mathcal{P}^*$ between the two events $D$ and $A$ maximizes the proper time $\Delta \tau$?

i | $D$ and $A$ are time-like separated $\Rightarrow \exists$ Inertial system $K' = K(D, A)$ with

$$[D]_{K'} = (t_D' = 0, \hat{x}_D' = \vec{0}) \text{ and } [A]_{K'} = (t_A', \hat{x}_A' = \vec{0})$$  \hspace{1cm} (2.26)

That is, without loss of generality, we can Lorentz transform into an inertial system where the two events happen at the same location (and by translations we can assume that this location is the origin $\vec{0}$ and that the coordinate time is $t_D' = 0$ at $D$). We label the time and space coordinate in $K'$ by $t'$ and $\hat{x}'$. Because of the relativity principle $\text{SR}$, $K'$ is as good as any system to describe events.

ii | Time of an arbitrary path $\mathcal{P} \ni D, A$ with $[\mathcal{P}]_{K'} = (t', \hat{x}'(t'))$:

$$\Delta \tau[\mathcal{P}] = \int_{t_D'}^{t_A'} dt' \sqrt{1 - \frac{v'(t')^2}{c^2}} \leq \int_{t_D'}^{t_A'} dt' = t_A' - t'_D = \Delta \tau[\mathcal{P}^*]$$  \hspace{1cm} (2.27)
Here \( P^* \) is the trajectory between \( D \) and \( A \) that is parametrized by the constant function \( \vec{x}(t') = \vec{0} \) in \( K' \). In other inertial systems, this trajectory will not be constant; however, it is inertial, i.e., \( P^* \) is described by a trajectory between \( D \) and \( A \) with uniform velocity.

Check this by applying a Lorentz transformation to the coordinates \((t', \vec{0})_{K'}\):

\[ \rightarrow \text{Clocks that travel along the inertial trajectory } \mathcal{P}^* \text{ between } D \text{ and } A \text{ collect the largest proper time } \tau^* = \Delta \tau[\mathcal{P}^*]. \]

Collecting the “largest time” means that the these clocks run the fastest.

5 | It is important to let this result sink in:

Let \( K' \) be the rest frame of earth (which is located in the origin \( \vec{0} \)) and consider two twins of age \( \tau_D \):

- Twin S departs with a Spaceship at \( D \), flies away from earth, turns around and returns to earth at \( A \). Twin S therefore follows a trajectory similar to \( \mathcal{P}_2 \) in the sketches above.
- Twin E stays on Earth. He follows the inertial trajectory \( \mathcal{P}^* \) in the sketches above.

We just proved above:

\[
\langle \text{Age of Twin S at } A \rangle = \Delta \tau[\mathcal{P}_2] + \tau_D < \Delta \tau[\mathcal{P}^*] + \tau_D = \langle \text{Age of Twin E at } A \rangle
\]

This is the famous \( \star \) Twin “paradox”: Twin S aged less than Twin E.

6 | Why there is no paradox:

- If you don’t see why the above result should be paradoxical:
  Good! Move along. Nothing to see here! 😊
- Why one could conclude that the above result is paradoxical (≈ logically inconsistent):
  - From the view of Twin E, Twin S speeds around quickly, thus time-dilation tells him that Twin S should age slower. And indeed, when Twin S returns, he actually didn’t age as much.
  - Now, you conclude, due to the relativity principle \( \text{SR} \), we could also take the perspective of Twin S (i.e., our system of reference is now attached to the spaceship). Then Twin S would conclude that time-dilation makes Twin E (who now, together with earth, speeds around quickly) age more slowly. But this does not match up with the above result that, when both twins meet again at \( A \), Twin S is the younger one! Paradox!

The result is quite straightforward:

The invocation of the relativity principle \( \text{SR} \) in the last point is not admissible! Remember that \( \text{SR} \) only makes claims about the equivalence of inertial systems. Now have a look at the trajectory \( \mathcal{P}_2 \) of the spaceship again: it is clearly accelerated and cannot be inertial. And that there is at least a period where the spaceship (and Twin S) is accelerating is a necessity for Twin S to return to Twin E (at least in flat spacetimes, but not so in curved ones [50])!

This implies that the reunion of both twins at \( A \) requires at least one of them to not stay in an inertial system. This breaks the symmetry between the two twins and explains why the result can be (and is) asymmetric.

- \( \star \) For historical (and anthropocentric) reasons, the “twin paradox” is called a “paradox.” We stick to this term because we have to – and not because it is appropriate name. The term “paradox” suggests an intrinsic inconsistency of relativity. As we explained above: This is not the case. All “paradoxes” in relativity are a consequence of unjustified, seemingly “intuitive” reasoning. The root cause is almost always an inappropriate, vague notion of “absolute simultaneity” that cannot be operationalized.
An overview on different geometric approaches to rationalize the phenomenon can be found in Ref. [51].

Below are two widely used spacetime diagrams of an idealized version where Twin S changes inertial systems only once from $S_D$ to $S_A$ halfway through the journey at $R$. You can think of this as an instantaneous acceleration at the kink. Note, however, that the acceleration itself is dynamically irrelevant for the arguments; it is only important that the inertial frames in which Twin S departs and returns are not the same:

- In the left diagram the slices of simultaneity in the two systems $S_D$ and $S_A$ are drawn. As predicted by time-dilation (and mandated by SR), Twin S observes the clocks of Twin E to run slower during his “inertial periods”, i.e., while he stays in a single inertial system. However, the moment Twin S “jumps” from $S_D$ to $S_A$ at $R$, his notion of simultaneity changes instantaneously: In $S_D$, $R$ and $R_D$ are simultaneous; in $S_A$, however, $R$ and $R_A$ are simultaneous. Due to this jump, the record of Twin S contains now a temporal gap for events on earth (highlighted interval). It is this “missing” time interval that overcompensates the slower running clocks on earth (as observed from $S_D$ and $S_A$) and makes Twin S conclude that Twin E ages faster (in agreement with the actual outcome of the experiment).

If you wonder what happened to the (missing) observations of events in the triangle $R_A R R_D$: there is a nice explanation in Schutz [4]. (The bottom line is that Twin S constructs a bad coordinate system by stopping the recording of events in system $S_D$ when he reaches $R$.)

- In the right diagram, we draw light signals (“pings”) of an earth-bound clock next to Twin E sent to Twin S. Twin S receives these signals and measures their period. This idealizes how Twin S sees (not observes!) the clocks ticking on earth (and, by proxy, how fast Twin E ages). It is important to understand the difference between this “seeing” and our operational definition of observing (using the contraption called an inertial system, as used in the left diagram). As demonstrated by the diagram, Twin S first sees the clock on earth ticking slower; but when he turns around at $R$, the clocks on earth (apparently) speed up significantly. In the end, this speedup overcompensates for the slowdown during the first part of the journey so that Twin S again arrives at the (correct) conclusion that Twin E ages faster. Note that the speedup of the earth-bound clock seen by Twin S during the second half of his journey does not contradict time-dilation...
because seeing is not observing. This is similar to the Penrose-Terrell effect in that a genuine relativistic effect (here: time-dilation) is distorted by an additional “imaging effect” due to the finite speed of light.

- In our careful derivation above, we not only showed that Twin S ages less than Twin E; we also showed that this conclusion is independent of the inertial observer! Thus we know that there will be no dispute about the different ages between different inertial observers.

- The Hafele-Keating experiment [46, 47] and the muon decay experiments [44], mentioned previously in the context of time-dilation, are experimental confirmations of the twin “paradox.” So our theoretical prediction above (that Twin S ages less than Twin E) is experimentally confirmed. End of discussion.

- Our derivation of the accumulated proper time along trajectories in spacetime is both mathematically sound and experimentally confirmed. This qualifies Special Relativity as a successful theory of physics. Operationally there is nothing to complain about: the theory does its job to produce quantitative predictions of real phenomena. So why do so many people (physicists included) – despite the various efforts to visualize the phenomenon – have this nagging feeling of dissatisfaction that they cannot get rid of? The reason, so I would argue, is the human brain and its proclivity to inject concepts of absolute simultaneity into its model building. This qualifies the historical overemphasis of the twin “paradox” as a meta problem: The question to study is not how to “solve” the twin “paradox” (as we showed above, there is nothing to solve); the question to study is why so many people thought (and still think) that there is a problem in the first place. This meta problem is an actual problem to study; but it falls into the domain of cognitive science, and not physics!

Two lessons to be learned from this:

- You can live longer than your inertial-system-dwelling peers by changing inertial systems (= accelerating) at least once.

The mere fact that our universe really allows for this (at least in theory) makes it much more interesting than its boring alternative: a Galilean universe.

and

- Phenomena like length contraction and the twin “paradox” are physically real. Their “paradoxical” flavor is a phenomenon of human cognition, not physics.

This is why we put “paradox” always in quotes in the context of Relativity.
3. Mathematical Tools I: Tensor Calculus

In this chapter we introduce tensor calculus (↑ *Ricci calculus*) for general coordinate transformations $\varphi$ (which will be useful both in *special relativity* and *general relativity*). The coordinate transformations $\varphi$ relevant for *special relativity* are Lorentz transformations (and therefore linear) which simplifies expressions often significantly (→ *Chapter 4*). However, this special feature of coordinate transformations in *special relativity* is not crucial for the discussions in this chapter.

**Goal:** Construct Lorentz covariant (form invariant) equations
(for mechanics, electrodynamics, quantum mechanics)

**Question:** How to do this systematically?

Note that (we suspect that) Maxwell equations are Lorentz covariant. Clearly this is not obvious and requires some work to prove; we say that the Lorentz covariance is *not manifest*: it is there, but it is hard to see. Conversely, without additional tools that make Lorentz covariance more obvious, it is borderline impossible to construct Lorentz covariant equations from scratch (which we must do for mechanics and quantum mechanics!).

We are therefore looking for a “toolkit” that provides us with elementary “building blocks” and a set of rules that can be used to construct Lorentz covariant equations. This toolbox is known as *tensor calculus* or ↑ *Ricci calculus*; the “building blocks” are tensor fields and the rules for their combination are given by index contractions, covariant derivatives, etc. The rules are such that the expressions (equations) you can build with tensor fields are *guaranteed* to be Lorentz covariant. This implies in particular that if you can rewrite any given set of equations (like the Maxwell equations) in terms of these rules, you automatically show that the equations were Lorentz covariant all along. We then say that the Lorentz covariance is *manifest*: one glance at the equation is enough to check it.

Later, in *general relativity*, our goal will be to construct equations that are invariant under arbitrary (differentiable) coordinate transformations (not just global Lorentz transformations). Luckily, the formalism we introduce in this chapter is powerful enough to allow for the construction of such *general covariant* equations as well. This is why we keep the formalism in this chapter as general as possible, and specialize it to *special relativity* in the next Chapter 4. The discussion below is therefore already a preparation for *general relativity*; it is based on Schröder [1] and complemented by Carroll [52].

3.1. Manifolds, charts and coordinate transformations

1 | *D*-dimensional Manifold
   = Topological space that *locally* “looks like” *D*-dimensional Euclidean space $\mathbb{R}^D$:
   
   ![Diagram of a manifold homeomorphic to $\mathbb{R}^3$](image)
In relativity, the manifold of interest is the set of coincidence classes \( \mathcal{E} \); it makes up the \( D = 4 \)-dimensional manifold we call spacetime.

A space that “locally looks like \( \mathbb{R}^D \)” is formalized as a \( \uparrow \) topological space that is locally \( \uparrow \) homeomorphic to Euclidean space \( \mathbb{R}^D \). The structure defined in this way is then called a \( \uparrow \) topological manifold.

## Differentiable Manifolds:

We want to formalize this idea and introduce additional structure to the manifold so that we can differentiate functions on it:

**i** Coordinate system / Chart \( (U, u) \):

\[
\begin{align*}
  u : & \quad U \subseteq M \rightarrow u(U) \subseteq \mathbb{R}^D \quad (3.1a) \\
  u^{-1} : & \quad u(U) \subseteq \mathbb{R}^D \rightarrow U \subseteq M \quad (3.1b)
\end{align*}
\]

\( U \subseteq M \): open subset of \( M \); \( u \) and \( u^{-1} \) are continuous and \( u \circ u^{-1} = 1 \).

\( U = M \) is allowed. This is the situation we assumed so far in special relativity: Our inertial coordinate systems cover all of spacetime \( M = \mathcal{E} \).

**ii** Two charts \( (U, v) \) and \( (V, v) \) and let \( U \cap V \neq \emptyset \):

\[
\begin{align*}
  \varphi := & \quad v \circ u^{-1} : u(U \cap V) \rightarrow v(U \cap V) \quad (3.2a) \\
  \varphi^{-1} := & \quad u \circ v^{-1} : v(U \cap V) \rightarrow u(U \cap V) \quad (3.2b)
\end{align*}
\]

\( \varphi \): Coordinate transformation / Transition map

\( U = M = V \) and \( U \cap V = M \) is allowed. This is the situation we assume so far in special relativity where \( (U = \mathcal{E}, u) \) and \( (V = \mathcal{E}, v) \) correspond to the coordinate systems of two different inertial systems. The coordinate transformation \( \varphi \) would then be a Lorentz transformation (defined on \( U \cap V = \mathcal{E} \)).

**iii** Atlas := Family of charts \( (U_i, u_i)_{i \in I} \) such that \( M = \bigcup_{i \in I} U_i \)

This definition of an atlas formalizes the notion of an atlas in real life (of the book variety): It contains many charts that, taken together, cover the complete manifold (typically earth). The different charts (on different pages of the book) all overlap on their edges such that you can draw any route on earth without gaps.

All \( \varphi, \varphi^{-1} \) differentiable \( \rightarrow M \): Differentiable Manifold

\[\text{PAGE 78}\]
• \( \varphi \) and \( \varphi^{-1} \) are maps from \( \mathbb{R}^D \) to itself. It is therefore clear what “differentiable” means.

• In mathematics one is of course more precise about the degree of differentiability of the transition functions, and subsequently assigns this degree to the manifold. For example, if all coordinate transformations are infinitely often differentiable (= smooth), the manifold is called a smooth manifold. We are sloppy in this regard: For us all functions are differentiable as often as we need them to be.

In relativity we will only be concerned with differentiable manifolds.

3 | Example:

→ In general, a manifold cannot be covered by a single chart (Earth, mathematically \( S^2 \), needs at least two charts). In special relativity this is not a problem: There we assume that spacetime is a flat (pseudo-)Euclidean space \( \mathbb{E}^4 \sim \mathbb{R}^4 \) and the coordinates given by our inertial systems cover all of spacetime. Later, in general relativity, this will not necessarily be the case.

3.2. Scalars

4 | \( \clubsuit \) Scalar (field) := Function \( \phi : M \rightarrow \mathbb{R}/\mathbb{C} \)

• If \( \phi \) maps to \( \mathbb{R} \) (\( \mathbb{C} \)), we call \( \phi \) a real (complex) scalar field.

• \( \clubsuit \) \( \phi \) is a geometric object because it only depends on the manifold itself. It does not rely on charts/coordinates and does not depend on a particular set of charts you might choose to parametrize the manifold. The notion of a mathematical object to be “geometric in nature” or “independent of the choice of coordinates” is absolutely crucial for the understanding of general relativity. The reason why these “geometric objects” are so important for physics is the following insight that took physicists (including Einstein) a long time to fully comprehend and implement mathematically:

> Coordinates (charts) do not represent physical entities. They are (useful) “mathematical auxiliary structures.”

• One reason why it is so hard for us to grasp and implement the “physical irrelevance” of coordinates is, so I believe, that the first (and often only) coordinates we encounter in school are Cartesian coordinates. They are particularly intuitive because they are simply the distances of a point to some coordinate axes. Distances are a geometric property and physically relevant
(you can measure them with rods); they are not the invention of mathematicians. This makes students draw the (wrong) conclusion that coordinates in general have intrinsic physical meaning. The problem is that coordinates are inventions of mathematicians; they do not share the ontological status of physical quantities like lengths etc. To undo this misconception is key to understand general relativity (→ much later).

• Since both $M$ and $\mathbb{R}/\mathbb{C}$ are topological spaces, it makes sense to ask whether (or require that) $\phi$ is continuous. It does not make sense to ask whether $\phi$ is differentiable (and what is derivative is) because, in general, $M$ does neither come with a notion of “distance” between two points in $M$ nor can you add or subtract points ($M$ does not have to be a metric space and/or a linear space). So an expression like $\partial_p \phi(p)$ does not make sense (→ below)!

We just declared that coordinates are “not physical.” The problem is that without coordinates it is really hard (at least for physicists) to do actual calculations with the geometric objects we are interested in (for example: compute derivatives). In addition, comparing theoretical predictions with experimental observations typically requires some sort of coordinate representation. Our inertial systems, for example, are elaborate measurement devices that produce a specific coordinate representation of the observed events.

This is why we always assume in the following that we have one (or more) charts that allow us to parametrize a (part of the) manifold, and then express the geometric quantities as functions of these coordinates. This means for the scalar field:

\begin{align}
\Phi(x) & := \phi(u^{-1}(x)) \quad x \in u(U \cap V) \\
\tilde{\Phi}(\tilde{x}) & := \phi(v^{-1}(\tilde{x})) \quad \tilde{x} \in v(U \cap V)
\end{align}

$\Phi$ and $\tilde{\Phi}$ are functions on (subsets of) $\mathbb{R}^D$; in contrast to $\phi$ which is a function on the manifold $M$.

In an abuse of notation, some authors do not make this distinction and write $\phi$ and $\tilde{\phi}$ instead.

\begin{align}
\tilde{\Phi}(\tilde{x}) = \Phi(x) \quad \text{for} \quad \tilde{x} = \varphi(x) \quad \text{with} \quad \varphi = v \circ u^{-1}.
\end{align}

Note that $\tilde{\Phi}(\tilde{x}) \equiv \phi(p) \equiv \Phi(x)$ with $u^{-1}(x) = p = v^{-1}(\tilde{x})$.

• In relativity we typically work in a particular chart (coordinate system). Thus we write our fields as functions of coordinates (and not points on the manifold); e.g., when working with scalars, we typically work with $\Phi$ (and not $\phi$).

• The special transformation of a field Eq. (3.4) (given as function of coordinates) tells us that it actually encodes a geometric, chart-independent function $\phi$ (given as function of points on the manifold). This idea will be prevalent throughout this chapter and is the basis of our modern formulation of relativity: We work with functions that depend on specific coordinates (and therefore change when we transition to another chart); however, these functions satisfy certain transformation laws [like Eq. (3.4)] that guarantee that they actually encode geometric, chart-independent objects (which is what physics is about).

• As a function of coordinates, scalar fields are those fields the values of which do not change under coordinate transformations. A typical example would be the temperature as a function of position: When you move your coordinate system, the temperature of a particular point in space still is the same (only your coordinates of this particular point have changed!). This is exactly what Eq. (3.4) demands.
Note that being a scalar (field) does not simply mean “being a number.” The $z$-component of the electric field strength $E_z(x)$, for example, assigns a number to every point $x$; however, it does not transform like Eq. (3.4) under coordinate transformations. (Do you see why? What happens to $E_z$ if you rotate your coordinate system?)

- In the literature, you will find the notation $\Phi = \Phi$ to characterize scalars. This does not mean $\Phi(x) = \Phi(x)$ for all $x \in \mathbb{R}^D$ (which characterizes form-invariance or functional equivalence), but rather $\Phi(\tilde{x}) = \Phi(x)$ (which characterizes scalar fields). Note that with $x = \varphi^{-1}(\tilde{x})$ it follows $\Phi(\tilde{x}) = \Phi(\varphi^{-1}(\tilde{x}))$ such that the function $\Phi$ is typically not functionally equivalent to $\Phi$. This ambiguity is the price we have to pay if we want to express geometric objects in terms of coordinates.

- Since $\Phi : \mathbb{R}^D \to \mathbb{R}$, it is well-defined what “differentiability” of $\Phi$ means. So expressions like $\frac{\partial \Phi(x)}{\partial x^i}$ make sense now (if $\Phi$ is differentiable). One then defines that $\phi$ is differentiable on $M$ iff $\Phi$ is differentiable for all charts of an atlas of $M$.

### 3.3. Covariant and contravariant vector fields

Are scalar fields the only geometric objects that can be defined on a manifold? The answer is no; there are many more! And these objects are not just toys for mathematicians: they are necessary to represent physical quantities like the electromagnetic field. Unfortunately, the definition of these quantities is not so straightforward as for scalars. We will not be mathematically precise in our discussion; however, it is important to understand the conceptual ideas:

6 | $\mathbb{R}^2$ **Tangent space** $T_pM$ at $p \in M$

= Vector space of directional derivative operators with evaluation at $p \in M$ ($=\text{derivations}$)

These operators can be applied to differentiable functions on the manifold (i.e., scalar fields).

- The tangent space $T_pM$ is the mathematical formalization of the intuitive concept of the plane $\mathbb{R}^2$ that you can attach tangentially at any point $p$ of a two-dimensional manifold. The problem with this picture is that it only works if you embed the manifold $M$ into a higher-dimensional Euclidean space. Mathematically, such an approach is not satisfying because it presupposes additional structure to characterize the manifold (which, as it turns out, is not needed). Physically, the approach is also problematic: The manifold we are interested in is all of spacetime $E$. But $E$ is all there is, it is (to the best of our knowledge) not embedded into anything. It is therefore crucial that we can work with manifolds “stand alone”, without assuming any embedding into a higher-dimensional space. The price we have to pay is that tangent vectors must be defined, rather abstractly, as directional derivative operators.
There is a different tangent space $T_pM$ at every point $p \in M$; these vector spaces all have the same dimension $D$ (like the manifold) and are therefore all isomorphic. However, without additional structure, there is no natural connection (isomorphism) between these different vector spaces at different points. The disjoint union of all tangent spaces is called the tangent bundle $TM$.

Mathematically, the vectors in the tangent space can be defined as equivalence classes of smooth curves through $p$ with the same derivative (with respect to their parametrization) at $p$. This equivalence class corresponds to a particular directional derivative that one can apply to smooth functions on the manifold at $p$. We do not need this abstract “bootstrapping procedure” for $T_pM$ in the following.

Chart $(U, u)$ with coordinates $x = (x^0, x^1, \ldots, x^D)$

Coordinate basis $\{\partial_i = \frac{\partial}{\partial x^i}\}$ for $T_pM$

Recall that partial derivatives are special kinds of directional derivatives (namely in the direction where you keep all but one coordinate fixed). You can therefore think of $\partial_i$ as the tangent vector at $p \in M$ that points into the $x^i$-direction mapped by $u^{-1}$ onto the manifold.
